PINFER: Privacy-Preserving Inference for Machine Learning*
Logistic Regression, Support Vector Machines, and More, Over Encrypted Data

Marc Joye and Fabien A. P. Petitcolas
OneSpan, Brussels, Belgium
{marc.joye,fabien.petitcolas}@onespan.com

Abstract. The foreseen growing role of outsourced machine learning services is raising concerns about the privacy of user data. Several technical solutions are being proposed to address the issue. Hardware security modules in cloud data centres appear limited to enterprise customers due to their complexity, while general multi-party computation techniques require a large number of message exchanges. This paper proposes a variety of protocols for privacy-preserving regression and classification that (i) only require additively homomorphic encryption algorithms, (ii) limit interactions to a mere request and response, and (iii) that can be used directly for important machine-learning algorithms such as logistic regression and SVM classification. The basic protocols are then extended and applied to feed-forward neural networks.

Keywords: Machine learning as a service · Linear regression · Logistic regression · Support vector machines · Feed-forward neural networks · Data privacy · Additively homomorphic encryption

1 Introduction

The popularity and hype around machine learning, combined with the explosive growth of user-generated data, is pushing the development of machine learning as a service (MLaaS). A typical application scenario of MLaaS is shown in Fig. 1. It involves a client sending data to a service provider (server) owning and running a trained machine learning model for a given task (e.g., medical diagnosis). Both the input data and the model should be kept private: for obvious privacy reasons on the client’s side and to protect intellectual property on the server’s side.

![Fig. 1: A server offering MLaaS owns a model defined by its parameters \( \theta \). A client needs the prediction \( h_\theta(x) \) of this model for a new input data \( x \). This prediction is a function of the model and of the data.](image)

In this paper we look at various protocols allowing the realisation of such scenario in a minimum number of message exchanges between both parties. Our assumption is that both the client and the server are honest.

* This is an extended version of [19].
but curious, that is, they both follow the protocol but may record information all along with the aim, respectively, to learn the model and to breach the client’s privacy. Our design is guided by the following ideal requirements, in decreasing importance:

1. **Input confidentiality**—The server does not learn anything about the input data $x$ provided by the client;
2. **Output confidentiality**—The server does not learn the outcome $\hat{y}$ of the calculation;
3. **Minimal model leakage**—The client does not learn any other information about the model beyond what is revealed by the successive outputs.

With respect to the issue of model leakage, it is noted that the client gets access to the outcome, i.e., the value of $h_\theta(x)$, which may leak information about $\theta$, violating Requirement 3. This is unavoidable and not considered as an attack within our framework. Possible countermeasures to limit the leakage on the model include rounding the output or adding some noise to it [29].

**Related Work** Earliest works for private machine learning evaluation [3,23] were concerned with training models in a privacy-preserving manner. More recent implementations for linear regression, logistic regression, as well as neural networks are offered by SecureML [25]. The case of support vector machines (SVM) is, for example, covered in [32]. On the contrary, this paper deals with the problem of privately *evaluating* a linear machine-learning model, including linear/logistic regression and SVM classification. In [7], Bos et al. suggest to evaluate a logistic regression model by replacing the sigmoid function with its Taylor series expansion. They then apply fully homomorphic encryption so as to get the output result through a series of multiplications and additions over encrypted data. They observe that using terms up to degree 7 the Taylor expansion gives roughly two digits of accuracy to the right decimal. Kim et al. [21] argue that such an expansion does not provide enough accuracy on real-world data sets and propose another polynomial approximation. For SVM classification, Zhang et al. [32, Protocol 2] propose to return an encryption of the raw output. The client decrypts it and applies the discriminating function to obtain the corresponding class. Unfortunately, this leaks more information than necessary on the model. A similar path is taken by Barni et al. in [6] for feed-forward neural networks. Extracting the model (even partially) is nevertheless more difficult in their case because of the inherent complexity of the model. Moreover, to further obfuscate it (and thereby limit the potential leakage), the authors suggest to randomly permute computing units (neurons) sharing the same activation function or to add dummy ones. For classification, the approach put forward by Bost et al. [8] is closest to ours. They construct three classification protocols fulfilling our design criteria (Requirements 1–3): hyperplane decision, naive Bayes, and decision trees. An approach orthogonal to ours that introduces privacy in regression or classification is differential privacy [11]. Crucially, it can be combined with secure computation, in our case by incorporating noise in the input vectors or in the model parameters. Differential privacy can thus be used to enhance the privacy properties of our protocols.

**Our Contributions** Our paper follows the line of work by Bost et al., making use only of additively homomorphic encryption (i.e., homomorphic encryption supporting additions). We devise new privacy-preserving protocols for a variety of important prediction tasks. The protocols we propose either improve on [8] or address machine-learning models not covered in [8]. In particular, we aim at minimising the number of message exchanges to a mere request and response. This is important when latency is critical. An application of [8, Protocol 4] to binary SVM classification adds a round-trip to the comparison protocol whereas our implementation optimally only needs a single round-trip, all included. Likewise, a single round-trip is needed in our private logistic regression protocol, as in [7,32]. But contrary to [7,32], the resulting prediction is *exact* in our case (i.e., there is no loss of accuracy) and does not require the power of fully homomorphic encryption. With respect to neural networks, we adapt our protocols to binarised networks and to networks relying of the popular ReLU activation; see Section 4.2. As far as we know, this results in the first privacy-preserving implementation of the non-linear ReLU function from additively homomorphic encryption.
Organisation The rest of this paper is organised as follows. In Section 2, we give a short summary of important machine learning techniques for which we will propose secure protocols. We also recall cryptographic tools on which we will build out protocols. In Section 3, we propose three families of protocols for private inference. They do not depend on a particular additively homomorphic encryption scheme. We next apply in Section 4 our protocols to the private evaluation of neural networks. Finally, the paper concludes in Section 6.

2 Preliminaries

This section reviews some important machine learning models, which all rely on the computation of an inner product. It also introduces building blocks that are necessary in the subsequent design of our privacy-preserving protocols.

2.1 Linear Models and Beyond

Owing to their simplicity, linear models (see, e.g., [2, Chapter 3] or [17, Chapters 3 and 4]) should not be overlooked: They are powerful tools for a variety of machine learning tasks and find numerous applications.

Problem Setup In a nutshell, machine learning works as follows. Each particular problem instance is characterised by a set of $d$ features which may be viewed as a vector $(x_1, \ldots, x_d)^\top$ of $\mathbb{R}^d$. For practical reasons, a fixed coordinate $x_0 = 1$ is added. We let $\mathcal{X} \subseteq \{1\} \times \mathbb{R}^d$ denote the input space and $\mathcal{Y}$ the output space. Integer $d$ is called the dimensionality of the input data.

There are two phases:

- The learning phase consists in approximating a target function $f : \mathcal{X} \rightarrow \mathcal{Y}$ from $\mathcal{D} = \{(x_i, y_i) \in \mathcal{X} \times \mathcal{Y} | y_i = f(x_i)\}_{1 \leq i \leq n}$, a training set of $n$ pairs of elements. Note that the target function can be noisy. The output of the learning phase is a function $h_{\theta} : \mathcal{X} \rightarrow \mathcal{Y}$ drawn from some hypothesis set of functions.
- In the testing phase, when a new data point $x \in \mathcal{X}$ comes in, it is evaluated on $h_{\theta}$ as $\hat{y} = h_{\theta}(x)$. The hat on $y$ indicates that it is a predicted value.

Since $h_{\theta}$ was chosen in a way to “best match” $f$ on the training set $\mathcal{D}$, it is expected that it will provide a good approximation on a new data point. Namely, we have $h_{\theta}(x_i) \approx y_i$ for all $(x_i, y_i) \in \mathcal{D}$ and we should have $h_{\theta}(x) \approx f(x)$ for $(x, \cdot) \notin \mathcal{D}$. Of course, this highly depends on the problem under consideration, the data points, and the hypothesis set of functions.

In particular, linear models for machine learning use a hypothesis set of functions of the form $h_{\theta}(x) = g(\theta^\top x)$ where $\theta = (\theta_0, \theta_1, \ldots, \theta_d)^\top \in \mathbb{R}^{d+1}$ are the model parameters and $g : \mathbb{R} \rightarrow \mathcal{Y}$ is a function mapping the linear calculation to the output space.

When the range of $g$ is real-valued and thus the prediction result $\hat{y} \in \mathcal{Y}$ is a continuous value (e.g., a quantity or a probability), we talk about regression. When the prediction result is a discrete value (e.g., a label), we talk about classification. An important sub-case is $\mathcal{Y} = \{+1, -1\}$. Specific choices for $g$ are discussed in the next sections.

Linear Regression A linear regression model assumes that the real-valued target function $f$ is linear—or more generally affine—in the input variables. In other words, it is based on the premise that $f$ is well approximated by an affine map; i.e., $g$ is the identity map: $f(x_i) \approx g(\theta^\top x_i) = \theta^\top x_i$, $1 \leq i \leq n$, for training data $x_i \in \mathcal{X}$ and weight vector $\theta \in \mathbb{R}^{d+1}$. This vector $\theta$ is interesting as it reveals how the output depends on the input variables. In particular, the sign of a coefficient $\theta_j$ indicates either a positive or a negative contribution to the output, while its magnitude captures the relative importance of this contribution.

The linear regression algorithm relies on the least squares method to find the coefficients of $\theta$: it minimises the sum of squared errors $\sum_{i=1}^n (f(x_i) - \theta^\top x_i)^2$. Once $\theta$ has been computed, it can be used to produce estimates on new data points $x \in \mathcal{X}$ as $\hat{y} = \theta^\top x$. 

Support Vector Machines  We now turn our attention to another important problem: how to classify data into different classes. This corresponds to a target function \( f \) whose range \( \mathcal{Y} \) is discrete. Of particular interest is the case of two classes, say \(+1\) and \(-1\), in which case \( \mathcal{Y} = \{+1, -1\} \). Think for example of a binary decision problem where \(+1\) corresponds to a positive answer and \(-1\) to a negative answer.

In dimension \( d \), an hyperplane \( \Pi \) is given by an equation of the form \( \theta_0 + \theta_1 x_1 + \theta_2 x_2 + \cdots + \theta_d x_d = 0 \) where \( \theta' = (\theta_1, \ldots, \theta_d)^\top \) is the normal vector to \( \Pi \) and \( \theta_0/\|\theta'\| \) indicates the offset from the origin.

When the training data are linearly separable, there is some hyperplane \( \Pi \) such that for each \((x_i, y_i) \in \mathcal{D}, \) one has
\[
\begin{cases}
\theta_0 + \theta_1 x_{i,1} + \theta_2 x_{i,2} + \cdots + \theta_n x_{i,d} > 0 & \text{if } y_i = +1 \\
\theta_0 + \theta_1 x_{i,1} + \theta_2 x_{i,2} + \cdots + \theta_n x_{i,d} < 0 & \text{if } y_i = -1
\end{cases}, \quad 1 \leq i \leq n, \quad (1)
\]
or equivalently (by scaling \( \theta \) appropriately):
\[
y_i \theta^\top x_i \geq 1, \quad (1 \leq i \leq n). \quad (2)
\]
The training data points \( x_i \) satisfying \( y_i \theta^\top x_i = 1 \) are called support vectors.

When the training data are not linearly separable, it is not possible to satisfy the previous hard constraint \( y_i \theta^\top x_i \geq 1, \) \( 1 \leq i \leq n \). So-called “slack variables” \( \xi_i = \max(0, 1 - y_i \theta^\top x_i) \) are generally introduced in the optimisation problem. They tell how large a violation of the hard constraint there is on each training point—note that \( \xi_i = 0 \) whenever \( y_i \theta^\top x_i \geq 1 \).

There are many possible choices for \( \theta \). For better classification, the separating hyperplane \( \Pi \) is chosen so as to maximise the margin; namely, the minimal distance between any training data point and \( \Pi \). Now, from the resulting model \( \theta \), when a new data point \( x \) comes in, its class is estimated as the sign of the discriminating function \( \theta^\top x \); i.e., \( \hat{y} = \text{sign}(\theta^\top x) \). Compare with Eq. (1).

When there are more than two classes, the optimisation problem returns several vectors \( \theta_k \), each defining a boundary between a particular class and all the others. The classification problem becomes an iteration to find out which \( \theta_k \) maximises \( \theta_k^\top x \) for a given test point \( x \).

Logistic Regression  Logistic regression is widely used in predictive analysis to output a probability of occurrence. The logistic function is defined by the sigmoid function
\[
\sigma: \mathbb{R} \to [0, 1], \ t \mapsto \sigma(t) = \frac{1}{1 + e^{-t}}. \quad (2)
\]
The logistic regression model returns \( h_\theta(x) = \sigma(\theta^\top x) \in [0, 1] \), which can be interpreted as the probability that \( x \) belongs to the class \( y = +1 \). The SVM classifier thresholds the value of \( \theta^\top x \) around 0, assigning to \( x \) the class \( y = +1 \) if \( \theta^\top x > 0 \) and the class \( y = -1 \) if \( \theta^\top x < 0 \). In this respect, the logistic function is seen as a soft threshold as opposed to the hard threshold, +1 or −1, offered by SVM. Other threshold functions are possible. Another popular soft threshold relies on tanh, the hyperbolic tangent function, whose output range is \([-1, 1]\).

Remark 1. Because the logistic regression algorithm predicts probabilities rather than just classes, we fit it through likelihood optimisation. Specifically, given the training set \( \mathcal{D} \), we learn the model by maximising \( \prod_{y_i=+1} p_i \cdot \prod_{y_i=-1} (1 - p_i) \) where \( p_i = \sigma(\theta^\top x_i) \). This deviates from the general description of our problem setup, where the learning is directly done on the pairs \((x_i, y_i)\). However, the testing phase is unchanged: the outcome is expressed as \( h_\theta(x) = \sigma(\theta^\top x) \). It therefore fits our framework for private inference, that is, the private evaluation of \( h_\theta(x) = g(\theta^\top x) \) for a certain function \( g \); the sigmoid function \( \sigma \) in this case.

2.2 Cryptographic Tools

Representing Real Numbers  So far, we have discussed a number of machine learning models using real numbers, but the cryptographic tools we intend to use require working on integers. We therefore start by
recalling the necessary conversion. An encryption algorithm takes as input an encryption key and a plaintext message and returns a ciphertext. We let \( M \subset \mathbb{Z} \) denote the set of messages that can be encrypted. In order to operate over encrypted data, we need to accurately represent real numbers as elements of \( M \) (i.e., a finite subset of \( \mathbb{Z} \)).

To do that, since all input variables of machine learning models are typically rescaled in the range \([-1, 1]\], one could use a fixed point representation. A real number \( x \) with a fractional part of at most \( P \) bits uniquely corresponds to signed integer \( z = x \cdot 2^P \). Hence, with a fixed-point representation, a real number \( x \) is represented by

\[
z = \lfloor x \cdot 2^P \rfloor
\]

where integer \( P \) is called the bit-precision. The sum of \( x_1, x_2 \in \mathbb{R} \) is performed as \( z_1 + z_2 \) and their multiplication as \( \lfloor (z_1 \cdot z_2)/2^P \rfloor \).

**Additively Homomorphic Encryption** Homomorphic encryption schemes come in different flavours. Before Gentry’s breakthrough result ([13]), only addition operations or multiplication operations on ciphertexts—but not both—were supported. Schemes that can support an arbitrary number of additions and of multiplications are termed *fully* homomorphic encryption (FHE) schemes. Our privacy-preserving protocols only need an *additively* homomorphic encryption scheme. The minimal security notion that we require is semantic security [16]; in particular, encryption is probabilistic.

It is useful to introduce some notation. We let \( \llbracket \cdot \rrbracket \) and \( \llbracket \cdot \rrbracket \) denote the encryption and decryption algorithms, respectively. The message space is an additive group \( M \cong \mathbb{Z}/M\mathbb{Z} \). It consists of integers modulo \( M \) and we view it as \( M = \{-\lfloor M/2 \rfloor, \ldots, \lceil M/2 \rceil - 1 \} \) in order to keep track of the sign. The elements of \( M \) are uniquely identified with \( \mathbb{Z}/M\mathbb{Z} \) via the mapping \( \Upsilon: M \rightarrow \mathbb{Z}/M\mathbb{Z}, m \mapsto m \mod M \). The inverse mapping is given by \( Y^{-1}: \mathbb{Z}/M\mathbb{Z} \rightarrow M, m \mapsto m \mod M \) if \( m < \lfloor M/2 \rfloor \) and \( m \mapsto m - M \) otherwise. Ciphertexts are noted with Gothic letters. The encryption of a message \( m \in M \) is obtained using public key \( pk \) as \( m = \llbracket m \rrbracket_{pk} \). It is then decrypted using the matching secret key \( sk \) as \( m = \llbracket m \rrbracket_{sk} \). When clear from the context, we drop the \( pk \) or \( sk \) subscripts and sometimes use \( \llbracket \cdot \rrbracket_s \) and \( \llbracket \cdot \rrbracket_a \) to denote another encryption algorithm. If \( m = (m_1, \ldots, m_d) \in M^d \) is a vector, we write \( m = \llbracket m \rrbracket_a \) as a shorthand for \( (\llbracket m_1 \rrbracket_a, \ldots, \llbracket m_d \rrbracket_a) \).

Algorithm \( \llbracket \cdot \rrbracket_a \) being additively homomorphic (over \( M \)) means that given any two plaintext messages \( m_1 \) and \( m_2 \) and their corresponding ciphertexts \( \llbracket m_1 \rrbracket_a = \llbracket m_1 \rrbracket_a \) and \( \llbracket m_2 \rrbracket_a = \llbracket m_2 \rrbracket_a \), we have \( \llbracket m_1 \rrbracket_a \oplus \llbracket m_2 \rrbracket_a = \llbracket m_1 + m_2 \rrbracket_a \) and \( \llbracket m_1 \rrbracket_a \odot \llbracket m_2 \rrbracket_a = \llbracket m_1 \odot m_2 \rrbracket_a \) for some publicly known operations \( \oplus \) and \( \odot \) on ciphertexts. By induction, for a given integer scalar \( r \in \mathbb{Z} \), we also have

\[
\llbracket r \cdot m_1 \rrbracket_a = \llbracket m_1 + \cdots + m_1 \rrbracket_a = \llbracket m_1 \rrbracket_a \oplus \cdots \oplus \llbracket m_1 \rrbracket_a
\]

\[
= \llbracket m_1 \rrbracket_a \oplus \cdots \oplus \llbracket m_1 \rrbracket_a := r \odot \llbracket m_1 \rrbracket_a.
\]

It is worth noting here that the decryption of \( \llbracket m_1 \rrbracket_a \oplus \llbracket m_2 \rrbracket_a \) gives \( \lfloor m_1 + m_2 \rfloor_a \) as an element of \( M \); that is, \( \llbracket m_1 \rrbracket_a \oplus \llbracket m_2 \rrbracket_a \equiv m_1 + m_2 \pmod{M} \). Similarly, we also have \( \llbracket r \cdot m_1 \rrbracket_a \equiv m_1 \odot m_2 \pmod{M} \) and \( \llbracket r \odot \llbracket m_1 \rrbracket_a \equiv r \cdot m_1 \pmod{M} \).

**Private Comparison Protocol** In [9,10], Damgård et al. present a protocol for comparing private values. It was later extended and improved in [12] and [30,20]. The protocol makes use of an additively homomorphic encryption scheme. It compares two non-negative \( \ell \)-bit integers. The message space is \( M \cong \mathbb{Z}/M\mathbb{Z} \) with \( M \geq 2^{\ell} \) and is supposed to behave like an integral domain (for example, \( M \) a prime or an RSA-type modulus).

**DGK+ protocol** The setting is as follows. A client possesses a private \( \ell \)-bit value \( \mu = \sum_{i=0}^{\ell-1} \mu_i 2^i \) and a server possesses a private \( \ell \)-bit value \( \eta = \sum_{i=0}^{\ell-1} \eta_i 2^i \). They seek to respectively obtain bits \( \delta_c \) and \( \delta_s \) such that...
Remark 2. At this point, neither the client, nor the server, knows whether result, the first case yields \( \delta \) both) needs to reveal its share of secret sharing of the comparison bit across the client and the server as the correctness of the protocol follows from the fact that protocol [9], this modified comparison protocol is secure in the semi-honest model (i.e., against honest but curious adversaries). Interest-

3 Basic Protocols of Privacy-Preserving Inference

In this section, we present three families of protocols for private inference. They aim to satisfy the ideal requirements given in the introduction while keeping the number of exchanges to a bare minimum. Interestingly, they only make use of additively homomorphic encryption.

1 Given \([\mu_i]\), the server obtains \([\eta_i \oplus \mu_i]\) as \([\mu_i]\) if \(\eta_i = 0\), and as \([1] \equiv [\mu_i]\) if \(\eta_i = 1\).
We keep the general model presented in the introduction, but now work with integers only. The client holds \( \mathbf{x} = (1, x_1, \ldots, x_d)^\top \in \mathcal{M}^{d+1} \), a private feature vector, and the server possesses a trained machine-learning model given by its parameter vector \( \mathbf{\theta} = (\theta_0, \ldots, \theta_d)^\top \in \mathcal{M}^{d+1} \) or, in the case of feed-forward neural networks a set of matrices made of such vectors. At the end of protocol, the client obtains the value of \( g(\mathbf{\theta}^\top \mathbf{x}) \) for some function \( g \) and learns nothing else; the server learns nothing. To make the protocols easier to read, for a real-valued function \( g \), we abuse notation and write \( g(t) \) for an integer \( t \) assuming \( g \) also includes the conversion to real values; see Section 2.2. We also make the distinction between the encryption algorithm \( \lbrack \cdot \rbrack \) using the client’s public key and the encryption algorithm \( \lbrack \cdot \rbrack_s \), using the server’s public key and stress that, not only keys are different, but the algorithm could also be different. We use \( \lbrack \cdot \rbrack \) and \( \lbrack \cdot \rbrack_s \) for the respective corresponding decryption algorithms.

### 3.1 Private Linear/Logistic Regression

#### Private Linear Regression

As seen in Section 2.1, linear regression produces estimates using the identity map for \( g: \hat{y} = \mathbf{\theta}^\top \mathbf{x} \). Since \( \mathbf{\theta}^\top \mathbf{x} = \sum_{j=0}^d \theta_j x_j \) is linear, given an encryption \( \lbrack \mathbf{x} \rbrack \) of \( \mathbf{x} \), the value of \( \lbrack \mathbf{\theta}^\top \mathbf{x} \rbrack \) can be homomorphically evaluated, in a provably secure way [15].

Therefore, the client encrypts its feature vector \( \mathbf{x} \) under its public key with an additively homomorphic encryption algorithm \( \lbrack \cdot \rbrack \), and sends \( \lbrack \mathbf{x} \rbrack \) to the server. Using \( \mathbf{\theta} \), the server then computes \( \lbrack \mathbf{\theta}^\top \mathbf{x} \rbrack \) and returns it to the client. Finally, the client uses its private key to decrypt \( \lbrack \mathbf{\theta}^\top \mathbf{x} \rbrack = \lbrack \hat{y} \rbrack \) and gets the output \( \hat{y} \). This is straightforward and only requires one round of communication.

#### Private Logistic Regression

Things get more complicated for logistic regression. At first sight, it seems counter-intuitive that additively homomorphic encryption could suffice to evaluate a logistic regression model \( \sigma(t) \) over encrypted data. After all, the sigmoid function, \( \sigma(t) \), is non-linear.

The key observation is that the sigmoid function is **injective**:

\[
\sigma(t_1) = \sigma(t_2) \implies t_1 = t_2.
\]

So the client does not learn more about the model \( \mathbf{\theta} \) from \( t := \mathbf{\theta}^\top \mathbf{x} \) than it can learn from \( \hat{y} := \sigma(t) \) since the value of \( t \)! can be recovered from \( \hat{y} \) using \( t = \sigma^{-1}(\hat{y}) = \ln(\hat{y} / (1 - \hat{y})) \). Consequently, rather than returning an encryption of the prediction \( \hat{y} \), we let the server return an encryption of \( t \), without any security loss in doing so.

#### Our Core Protocol

The protocol we propose for privacy-preserving linear or logistic regression is detailed in Fig. 2. Let \( (pk_C, sk_C) \) denote the client’s matching pair of public encryption key/private decryption key for an additively homomorphic encryption scheme \( \lbrack \cdot \rbrack \). We use the notation of Section 2.2. If \( B \) is an upper bound on the inner product (in absolute value), the message space \( \mathcal{M} = \{- \lfloor M/2 \rfloor, \ldots, \lceil M/2 \rceil - 1\} \) should be such that \( M \geq 2B + 1 \).

In more detail, our core protocol goes as follows.

1. In a first step, the client encrypts its feature vector \( \mathbf{x} \in \mathcal{M}^{d+1} \) under its public key \( pk_C \) and gets \( \lbrack \mathbf{x} \rbrack = (\lbrack x_0 \rbrack, \lbrack x_1 \rbrack, \ldots, \lbrack x_d \rbrack) \). The ciphertext \( \lbrack \mathbf{x} \rbrack \) along with the client’s public key are sent to the server.
2. In a second step, from its model \( \mathbf{\theta} \), the server computes an encryption of the inner product over encrypted data as:

\[
t = \lbrack \mathbf{\theta}^\top \mathbf{x} \rbrack = \lbrack \theta_0 \rbrack \oplus \bigoplus_{j=1}^d \theta_j \odot \lbrack x_j \rbrack.
\]

The server returns \( t \) to the client.
3. In a third step, the client uses its private decryption key \( sk_C \) to decrypt \( t \), and gets the inner product \( t = \mathbf{\theta}^\top \mathbf{x} \) as a signed integer of \( \mathcal{M} \).
4. In a final step, the client applies the \( g \) function to obtain the prediction \( \hat{y} \) corresponding to input vector \( \mathbf{x} \).
Fig. 2: Privacy-preserving regression. Encryption is done using the client’s public key and noted \([x]\). The server learns nothing. Function \(g\) is the identity map for linear regression and the sigmoid function for logistic regression.

**Dual Approach** The previous protocol encrypts with the client’s public key \(pk_c\). In the dual approach, the server’s public key is used for encryption. Let \((pk_s, sk_s)\) denote the public/private key pair of the server for some additively homomorphic encryption scheme \(\{\cdot\}_s\). The message space \(\mathcal{M}\) is unchanged.

In this case, the server needs to publish an encrypted version \(\{\theta\}_s\) of its model. The client must therefore get a copy of \(\{\theta\}_s\) once, but can then engage in the protocol as many times as it wishes. One could also suppose that each client receives a different encryption of \(\theta\) using a server’s encryption key specific to the client, or that a key rotation is performed on a regular basis. This protocol uses a mask \(\mu\) which is chosen uniformly at random in \(\mathcal{M}\). Consequently, it is important to see that \(t^* (\equiv \theta^\top x + \mu \pmod M)\) is also uniformly distributed over \(\mathcal{M}\). Thus, the server gains no bit of information from \(t^*\). The different steps are summarised in Fig. 3.

Fig. 3: Dual approach for privacy-preserving regression. Here, encryption is done using the server’s public key \(pk_s\) and noted \([\cdot]_s\). Function \(g\) is the identity map for linear regression and the sigmoid function for logistic regression.
Variant and Extensions In a variant, in Step 2 of Fig. 2 (resp. Step 3 of Fig. 3), the server can add some noise $\epsilon$ by defining $t \leftarrow \mathbb{[}\theta^\top x + \epsilon] = \mathbb{[}\theta^\top x] \boxplus \mathbb{[}\epsilon]$ (resp. $t^* \leftarrow \mathbb{[}t^*]_s + \epsilon$). This presents the advantage of limiting the leakage on $\theta$ resulting from the output result. The proposed methods are not limited to the identity map or the sigmoid function but generalise to any injective function $g$. This includes the tanh activation function alluded to in Section 2.1 where $g(\theta) = \tanh(t/(1 + |t|))$.

This includes the tanh activation function alluded to in Section 2.1 where $g(\theta) = \tanh(t/(1 + |t|))$.

and more. For any injective function $g$, there is no more information leakage in returning $\theta^\top x$ than $g(\theta^\top x)$.

3.2 Private SVM Classification

As discussed in Section 2.1, SVM inference can be abridged to the evaluation of the sign of an inner product. However, the sign function is clearly not injective. Our idea is to make use of a privacy-preserving comparison protocol. For concreteness, we consider the DGK+ protocol; but any privacy-preserving comparison protocol could be adapted.

A Naive Protocol A client holding a private feature vector $x$ wishes to evaluate $\text{sign}(\theta^\top x)$ where $\theta$ parametrises an SVM classification model. In the primal approach, the client can encrypt $x$ and send $\mathbb{[}x]$ to the server. Next, the server computes $\mathbb{[}\eta] = \mathbb{[}\theta^\top x + \mu]$ for some random mask $\mu$ and sends $\mathbb{[}\eta]$ to the client. The client decrypts $\mathbb{[}\eta]$ and recovers $\eta$. Finally, the client and the server engage in a private comparison protocol with respective inputs $\eta$ and $\mu$, and the client deduces the sign of $\theta^\top x$ from the resulting comparison bit $[\mu \leq [\eta]]$.

There are two issues. If we use the DGK+ protocol for the private comparison, at least one extra exchange from the server to the client is needed for the client to get $[\mu \leq [\eta]]$. This can be fixed by considering the dual approach. A second, more problematic, issue is that the decryption of $\mathbb{[}\eta] := \mathbb{[}\theta^\top x + \mu]$ yields $\eta$ as an element of $\mathcal{M} \cong \mathbb{Z}/\mathbb{Z}$, which is not necessarily equivalent to the integer $\theta^\top x + \mu$. Note that if the inner product $\theta^\top x$ can take any value in $\mathcal{M}$, selecting a smaller value for $\mu \in \mathcal{M}$ to prevent the modular reduction does not solve the issue because the value of $\eta$ may then leak information on $\theta^\top x$.

Our Core Protocol Instead, we suggest to select the message space much larger than the upper bound $B$ on the inner product, so that the computation will take place over the integers. Specifically, if $\theta^\top x \in [-B, B]$ then, letting $\ell$ be the bit-length of $B$, the message space $\mathcal{M} = \{-\lfloor M/2 \rfloor, \ldots, \lceil M/2 \rceil - 1\}$ is dimensioned such that $\mathcal{M} \cong \mathbb{Z}/\mathbb{Z}$, which is not necessarily equivalent to the integer $\theta^\top x + \mu$. Let $\mu$ be an $(\ell + \kappa)$-bit integer that is chosen such that $\mu \geq B$. By construction we will then have $0 \leq \theta^\top x + \mu < M$ so that the decrypted value modulo $M$ corresponds to the actual integer value. As will become apparent, this presents the further advantage of optimising the bandwidth requirements: the number of exchanged ciphertexts depends on the length of $B$ and not on the length of $\mathcal{M}$ (notice that $\mathcal{M} = \#\mathcal{M}$).

Our resulting core protocol for private SVM classification of a feature vector $x$ is illustrated in Fig. 4 and includes the following steps:

0. The server publishes $pk_s$ and $\mathbb{[}\theta]_s$.
1. Let $\kappa$ be a security parameter. The client starts by picking uniformly at random in $[2^\ell - 1, 2^\ell + \kappa)$ an integer $\mu = \sum_{i=0}^{\ell + \kappa - 1} \mu_i 2^i$.
2. In a second step, the client computes, over encrypted data, the inner product $\theta^\top x$ and masks the result with $\mu$ to get $t^* = \mathbb{[}\theta_0]_s \boxplus \left( \bigoplus_{j=1}^d x_j \odot \mathbb{[}\theta_j]_s \right) \boxplus \mathbb{[}\mu]_s$.
3. Next, the client individually encrypts the first \( \ell \) bits of \( \mu \) with its own encryption key to get \( \llbracket \mu_i \rrbracket \), for \( 0 \leq i \leq \ell - 1 \), and sends \( t^* \) and the \( \llbracket \mu_i \rrbracket \)'s to the server.

4. Upon reception, the server decrypts \( t^* \) to get \( t^* := \llbracket t^* \rrbracket \mod M = \theta^T x + \mu \) and defines the \( \ell \)-bit integer \( \eta := t^* \mod 2^\ell \).

5. The DGK+ protocol is now applied to two \( \ell \)-bit values \( \mu := \mu \mod 2^\ell = \sum_{i=0}^{\ell-1} \mu_i 2^i \) and \( \eta = \sum_{i=0}^{\ell-1} \eta_i 2^i \).

The server selects the \((\ell + 1)\)th bit of \( t^* \) for \( \delta_s \) (i.e., \( \delta_s = \lfloor t^*/2^\ell \rfloor \mod 2 \)), defines \( s = 1 - 2\delta_s \), and forms the \( \|h_i^*\| \)'s (with \( -1 \leq i \leq \ell - 1 \)) as defined by Eq. (3). The server permutes randomly the \( \|h_i^*\| \)'s and sends them to the client.

6. The client decrypts the \( \|h_i^*\| \)'s and gets the \( h_i^* \)'s. If one of them is zero, it sets \( \delta_c = 1 \); otherwise it sets \( \delta_c = 0 \).

7. As a final step, the client obtains the predicted class as \( \hat{y} = (-1)^{-\langle \delta_c \oplus \mu \rangle} \), where \( \mu_\ell \) denotes bit number \( \ell \) of \( \mu \).

---

**Fig. 4:** Privacy-preserving SVM classification. Note that some data is encrypted using the client’s public key \( pk_C \), while other, is encrypted using the server’s public key \( pk_S \). They are noted \( \llbracket \cdot \rrbracket \) and \( \llbracket \cdot \rrbracket_s \) respectively.

Again, the proposed protocol keeps the number of interactions between the client and the server to a minimum: a request and a response.

**Correctness** To prove the correctness, we need the two following simple lemmata.

**Lemma 1.** Let \( a \) and \( b \) be two non-negative integers. Then for any positive integer \( n \), \( \lfloor (a - b)/n \rfloor = \lfloor a/n \rfloor - \lfloor b/n \rfloor + \lfloor (a \mod n) - (b \mod n) \rfloor/n \).

**Proof.** Write \( a = \lfloor a/n \rfloor n + (a \mod n) \) and \( b = \lfloor b/n \rfloor n + (b \mod n) \). Then \( a - b = (\lfloor a/n \rfloor - \lfloor b/n \rfloor)n + (a \mod n) - (b \mod n) \). Recalling that for \( n_0 \in \mathbb{Z} \) and \( x \in \mathbb{R} \), \( \lfloor x + n_0 \rfloor = \lfloor x \rfloor + n_0 \) and \( \lfloor -n_0 \rfloor = -\lfloor n_0 \rfloor \), the lemma follows by integer division through \( n \).

**Lemma 2.** Let \( a \) and \( b \) be two non-negative integers smaller than some positive integer \( n \). Then \( [b \leq a] = 1 + ((a - b)/n) \).
Proof. By definition $0 \leq a < n$ and $0 \leq b < n$. If $b \leq a$ then $0 \leq \frac{a-b}{n} < 1$ and thus $\lceil \frac{a-b}{n} \rceil = 0$; otherwise, if $b > a$ then $-1 < \frac{a-b}{n} < 0$ and so $\lceil \frac{a-b}{n} \rceil = -1$. \hfill ∎

Remember that, by construction, $\theta^T x \in [-B, B]$ with $B = 2^\ell - 1$, that $\mu \in [2^\ell - 1, 2^\ell + \kappa)$, and by definition that $t^* := \lceil t^*/2 \rceil$ mod $M$ with $t^* = \lceil (\theta^T x + \mu)/2 \rceil$. Hence, in Step 4, the server gets $t^* = \theta^T x + \mu$ mod $M = \theta^T x + \mu$ (over $\mathbb{Z}$) since $0 \leq \theta^T x + \mu \leq 2^\ell - 1 + 2^\ell + \kappa - 1 < M$. Let $\delta := \delta_c + \delta_s = [\mu \leq \eta]$ (with $\mu := \mu \mod 2^\ell$ and $\eta := t^* \mod 2^\ell$) denote the result of the private comparison in Steps 5 and 6 with the DGK+ protocol.

Either of those two conditions holds true
\[
\left\{ \begin{array}{ll}
0 \leq \theta^T x < 2^\ell & \iff 1 \leq \theta^T x + 2^\ell < 2 \iff \theta^T x + 2^\ell \leq \theta^T x + \mu = 1 \\
-2^\ell < \theta^T x < 0 & \iff 0 < \theta^T x + 2^\ell < 1 \iff \theta^T x + 2^\ell > \theta^T x + \mu = 0
\end{array} \right.,
\]
and so,
\[
[\theta^T x \geq 0] = \left\lceil \frac{\theta^T x + 2^\ell}{2^\ell} \right\rceil = \left\lfloor \frac{t^* - \mu}{2^\ell} \right\rfloor + 1 \quad \text{since } t^* = \theta^T x + \mu
\]
\[
= \left\lfloor \frac{t^*}{2^\ell} \right\rfloor - \left\lfloor \frac{\mu}{2^\ell} \right\rfloor + \left\lfloor \frac{\eta - \mu}{2^\ell} \right\rfloor + 1 \quad \text{by Lemma 1}
\]
\[
= \left\lfloor \frac{t^*}{2^\ell} \right\rfloor - \left\lfloor \frac{\mu}{2^\ell} \right\rfloor + \delta \\
= (\left\lfloor \frac{t^*}{2^\ell} \right\rfloor - \left\lfloor \frac{\delta}{2^\ell} \right\rfloor + \delta) \mod 2 \quad \text{since } [\theta^T x \geq 0] \in \{0, 1\}
\]
\[
= \left( \left\lfloor \frac{\mu}{2^\ell} \right\rfloor + \delta_c \right) \mod 2 \quad \text{since } \delta_s = [t^*/2^\ell] \mod 2
\]
\[
= \mu \ell + \delta_c.
\]
Now, noting $\text{sign}(\theta^T x) = (-1)^{[\theta^T x \geq 0]}$, we get the desired result.

Security The security of the protocol of Fig. 4 follows from the fact that the inner product $\theta^T x$ is statistically masked by the random value $\mu$. Security parameter $\kappa$ guarantees that the probability of an information leak due to a carry is negligible. The security also depends on the security of the DGK+ comparison protocol, which is provably secure (cf. Remark 2).

A Heuristic Protocol The previous protocol, thanks to the use of the DGK+ algorithm offers provable security guarantees but incurs the exchange of $2(\ell + 1)$ ciphertexts. Here we aim to reduce the number of ciphertexts and introduce a new heuristic protocol. This protocol requires the introduction of a signed factor $\lambda$, such that $|\lambda| > |\mu|$, and we now use both $\mu$ and $\lambda$ to mask the model. To ensure that $\lambda \theta^T x + \mu$ remains within the message space, we pick $\lambda$ in $\mathcal{B}$ where
\[
\mathcal{B} := \left\lfloor - \left\lceil \frac{M/2}{B + 1} \right\rceil , \left\lfloor \frac{M/2}{B + 1} \right\rfloor \right\rfloor.
\]
Furthermore, to ensure the effectiveness of the masking, $\mathcal{B}$ should be sufficiently large; namely, $\# \mathcal{B} > 2^\kappa$ for a security parameter $\kappa$, hence $M > 2^\ell (2^\kappa - 1)$.

The protocol, which is illustrated in Fig. 5, runs as follows:

1. The client encrypts its input data $x$ using its public key, and sends its key and the encrypted data to the server.
2. The server draws at random a signed scaling factor $\lambda \in \mathcal{B}$, $\lambda \neq 0$, and an offset factor $\mu \in \mathcal{B}$ such that $|\mu| < |\lambda|$ and $\text{sign}(\mu) = \text{sign}(\lambda)$. The server then defines the bit $\delta_s$ such that $\text{sign}(\lambda) = (-1)^{\delta_s}$ and computes an encryption $t^*$ of the shifted and scaled inner product $t^* = (-1)^{\delta_s} \cdot (\lambda \theta^T x + \mu)$ as
\[
t^* = \left\lfloor (-1)^{\delta_s} \mu \right\rfloor + \sum_{i=0}^{d} ((-1)^{\delta_s} \lambda \theta_i) \odot \|x_i\|,
\]

11
and sends $t^*$ to the client.\footnote{Note that instead, one could define $\lambda, \mu \in B$ with $\lambda > 0$ and $|\mu| < \lambda$, and $t^* = \lambda \theta^T x + \mu$. We however prefer the other formulation as it easily generalises to extended settings (see Section 4.1).}

3. In the final step, the client decrypts $t^*$ using its private key, recovers $t^*$ as a signed integer of $\mathcal{M}$, and deduces the class of the input data as $\hat{y} = \text{sign}(t^*)$.

---

![Fig. 5: Heuristic protocol for privacy-preserving SVM classification.](image)

**Correctness** The constraint $|\mu| < |\lambda|$ with $\lambda \neq 0$ ensures that $\hat{y} = \text{sign}(\theta^T x)$. Indeed, as $(−1)^{\delta_s} = \text{sign}(\lambda) = \text{sign}(\mu)$, we have $t^* = (−1)^{\delta_s} (\lambda \theta^T x + \mu) = |\lambda| \theta^T x + |\mu| = |\lambda|(\theta^T x + \epsilon)$ with $\epsilon := |\mu|/|\lambda|$. Hence, whenever $\theta^T x \neq 0$, we get $\hat{y} = \text{sign}(t^*) = \text{sign}(\theta^T x + \epsilon) = \text{sign}(\theta^T x)$ since $|\theta^T x| \geq 1$ and $|\epsilon| = |\mu|/|\lambda| < 1$. If $\theta^T x = 0$ then $\hat{y} = \text{sign}(\epsilon) = 1$.

**Security** We stress that the private comparison protocol we use in Fig. 5 does not come with formal security guarantees. In particular, the client learns the value of $t^* = \lambda \theta^T x + \mu$ with $\lambda, \mu \in \mathcal{B}$ and $|\mu| < |\lambda|$. Some information on $t := \theta^T x$ may be leaking from $t^*$ and, in turn, on $\theta$ since $x$ is known to the client. The reason resides in the constraint $|\mu| < |\lambda|$. So, from $t^* = \lambda \theta^T x + \mu$, we deduce $\log|t^*| \leq \log|\lambda| + \log(|t| + 1)$. For example, when $t$ has two possible very different “types” of values (say, very large and very small), the quantity $\log|t^*|$ can be enough to discriminate with non-negligible probability the type of $t$. This may possibly leak information on $\theta$. That does not mean that the protocol is necessarily insecure but it should be used with care.

**Remark 3.** The bandwidth usage could be even reduced to one ciphertext and a single bit with the dual approach. From the published encrypted model $\|\theta\|_s$, the client could homomorphically compute and send to the server $t^* = \|\lambda \theta^T x + \mu\|_s$ for random $\lambda, \mu \in \mathcal{B}$ with $|\mu| < |\lambda|$. The server would then decrypt $t^*$, obtain $t^*$, compute $\delta_s = \frac{1}{2}(1 - \text{sign}(t^*))$, and return $\delta_s$ to the client. Analogously to the primal approach, the output class $\hat{y} = \text{sign}(\theta^T x)$ is obtained by the client as $\hat{y} = (−1)^{\delta_s} \cdot \text{sign}(\lambda)$.

However, and contrarily to the primal approach, the potential information leakage resulting from $t^*$—in this case on $x$—is now on the server’s side, which is in contradiction with our Requirement 1 (input confidentiality). We do not further discuss this variant.
4 Application to Neural Networks

Typical feed-forward neural networks are represented as large graphs. Each node on the graph is often called a unit, and these units are organised into layers. At the very bottom is the input layer with a unit for each of the coordinates \( x^{(0)}_j \) of the input vector \( \mathbf{x}^{(0)} := \mathbf{x} \in \mathcal{X} \). Then various computations are done in a bottom-to-top pass and the output \( \hat{y} \in \mathcal{Y} \) comes out all the way at the very top of the graph. Between the input and output layers, a number of hidden layers are evaluated. We index the layers with a superscript \( (l) \), where \( l = 0 \) for the input layer and \( 1 \leq l < L \) for the hidden layers. Layer \( L \) corresponds to the output. Each unit of each layer has directed connections to the units of the layer below; see Fig. 6a.

![Diagram of a feed-forward neural network](image)

(a) Going from layer \( l - 1 \) to layer \( l \).

![Zoom on computing unit](image)

(b) Zoom on computing unit \( j \) in layer \( l \).

Fig. 6: Relationship between a hidden unit in layer \( l \) and the hidden units of layer \( l - 1 \) in a feed-forward neural network.

Figure 6b details the outcome \( x_j^{(l)} \) of the \( j \)th computing unit in layer \( l \). We keep the convention \( x_0^{(l)} := 1 \) for all layers. If we note \( \theta_j^{(l)} \) the vector of weight coefficients \( \theta_{j,k}^{(l)} \), \( 0 \leq k \leq d_{l-1} \), where \( d_l \) is the number of units in layer \( l \), then \( x_j^{(l)} \) can be expressed as:

\[
x_j^{(l)} = g_j^{(l)} \left( \theta_j^{(l)} \right)^\top \mathbf{x}^{(l-1)} = g_j^{(l)} \left( \theta_{j,0}^{(l)} + \sum_{k=1}^{d_{l-1}} \theta_{j,k}^{(l)} x_k^{(l-1)} \right), \quad 1 \leq j \leq d_l, \ 1 \leq l \leq L.
\] (4)

Functions \( g_j^{(l)} \) are non-linear functions such as the sign function or the Rectified Linear Unit (ReLU) function

\[
t \mapsto \begin{cases} 
t & \text{if } t \geq 0 \\ 0 & \text{otherwise} \end{cases} \quad g(t) \xrightarrow{t} t
\]
Those functions are known as activation functions. Other examples of activation functions are defined in Section 3.1. The weight coefficients characterise the model and are known only to the owner of the model. Each hidden layer depends on the layer below, and ultimately on the input data $x^{(0)}$, known solely to the client.

**Generic Solution** A generic solution can easily be devised from Eq. (4): for each inner product computation, and therefore for each unit of each hidden layer, the server computes the encrypted inner product and the client computes the output of the activation function in the clear. In more detail, the evaluation of a neural network can go as follows.

0. The client starts by encrypting its input data and sends it to the server.
1. Then, as illustrated in Fig. 7, for each hidden layer $l$, $1 \leq l < L$:
   (a) The server computes $d_l$ encrypted inner products $t_j$ corresponding to each unit $j$ of the layer and sends those to the client.
   (b) The client decrypts the inner products, applies the required activation function $g_j^{(l)}$, re-encrypts, and sends back $d_l$ encrypted values.
2. During the last round ($l = L$), the client simply decrypts the $t_j$ values and applies the corresponding activation function $g_j^{(L)}$ to each unit $j$ of the output layer. This is the required result.

![Fig. 7: Generic solution for privacy-preserving evaluation of feed-forward neural networks. Evaluation of hidden layer $l$.](image)

For each hidden layer $l$, exactly two messages (each comprising $d_l$ encrypted values) are exchanged. The input and output layers only involve one exchange; from the client to the server for the input layer and from the server back to the client for the output layer.

Several variations are considered in [6]. For increased security, provided that the units feature the same type of activation functions in a given layer $l$ (i.e., $g_1^{(l)} = g_2^{(l)} = \cdots = g_{d_l}^{(l)}$), the server may first apply a random permutation on all units (i.e., sending the $t_j$’s in a random order). It then recovers the correct ordering by applying the inverse permutation on the received $[x_j^{(l)}]$’s. The server may also want to hide the activation functions. In this case, the client holds the raw signal $t_j := t_j^{(l)} = (\theta_j^{(l)})^\top x$ and the server the
corresponding activation function \( g_j^{(l)} \). The suggestion of [6] is to approximate the activation function as a polynomial and to rely on oblivious polynomial evaluation [26] for the client to get \( x_j^{(l)} \approx P_j^{(l)}(t_j) \) without learning polynomial \( P_j^{(l)} \) approximating \( g_j^{(l)} \). Finally, the server may desire not to disclose the topology of the network. To this end, the server can distort the client’s perception by adding dummy units and/or layers.

In the following two sections, we improve this generic solution for two popular activation functions: the sign and the ReLU functions. In the new proposed implementations, everything is kept encrypted—from start to end. The raw signals are hidden from the client’s view in all intermediate computations.

### 4.1 Sign Activation

Binarised neural networks implement the sign function as activation function. This is very advantageous from a hardware perspective [18].

Section 3.2 describes two protocols for the client to get the sign of \( \theta^\top x \). In order to use them for binarised neural networks in a setting similar to the generic solution, the server needs to get an encryption of \( \text{sign}(\theta^\top x) \) for each computing unit \( j \) in layer \( l \) under the client’s key from \( [x] \), where \( [x] := [x^{(l-1)}] \) is the encrypted output of layer \( l-1 \) and \( \theta := \theta_j^{(l)} \) is the parameter vector for unit \( j \) in layer \( l \).

We start with the core protocol of Fig. 4. It runs in dual mode and therefore uses the server’s encryption. Exchanging the roles of the client and the server almost gives rise to the sought-after protocol. The sole extra change is to ensure that the server gets the classification result encrypted. This can be achieved by masking the value of \( \delta_c \) with a random bit \( b \) and sending an encryption of \((-1)^b\) \( \delta_c \). The resulting protocol is depicted in Fig. 8a.

In the heuristic protocol (cf. Fig. 5), the server already gets an encryption of \( [x] \) as an input. It however fixes the sign of \( t^* \) to that of \( \theta^\top x \). If now the server flips it in a probabilistic manner, the output class (i.e., \( \text{sign}(\theta^\top x) \)) will be hidden from the client’s view. We detail below the modifications to be brought to the heuristic protocol to accommodate the new setting:

- In Step 2 of Fig. 5, the server keeps private the value of \( \delta_s \) by replacing the definition of \( t^* \) with \( t^* = [\lambda \theta^\top x + \mu] \).
- In Step 3 of Fig. 5, the client then obtains \( \hat{y}^* := \text{sign}(\theta^\top x) \cdot (-1)^\delta_s \) and returns its encryption \( [\hat{y}^*] \) to the server.
- The server obtains \( [\hat{y}] \) as \( [\hat{y}] = (-1)^\delta_s \odot [\hat{y}^*] \).

If \( \theta := \theta_j^{(l)} \) and \( [x] := [x^{(l)}] \) then the outcome of the protocol of Fig. 8a or of the modified heuristic protocol is \( [\hat{y}] = [x^{(l)}] \). Of course, this can be done in parallel for all the \( d_l \) units of layer \( l \) (i.e., for \( 1 \leq j \leq d_l \); see Eq. (4)), yielding \( [x^{(l)}] = ([1], [x_1^{(l)}], \ldots, [x_{d_l}^{(l)}]) \). This means that just one round of communication between the server and the client suffices per hidden layer.

### 4.2 ReLU Activation

A widely used activation function is the ReLU function. It allows a network to easily obtain sparse representations and features cheaper computations as there is no need for computing the exponential function [14].

The ReLU function can be expressed from the sign function as

\[
\text{ReLU}(t) = \frac{1}{2} (1 + \text{sign}(t)) \cdot t .
\]  
(5)

Back to our setting, the problem is for the server to obtain \( [\text{ReLU}(t)] \) from \( [t] \), where \( t = \theta^\top x \) with \( x := x^{(l-1)} \) and \( \theta := \theta_j^{(l)} \), in just one round of communication per hidden layer. We saw in the previous section how to do it for the sign function. The ReLU function is more complex to apprehend. If we use Equation (5), the difficulty is to let the server evaluate a product over encrypted data. To get around that, the server super-encrypts \( [\theta^\top x] \), gets \( [\prod [\theta^\top x]] \), and sends it the client. According to its secret share the client sends back the
\[ \begin{align*}
\mu & \overset{R}{\leftarrow} [2^\ell - 1, 2^\ell + \kappa) \\
\lambda & \overset{R}{\leftarrow} B, \lambda \neq 0, |\mu| < |\lambda| \\
\delta_s & \leftarrow \frac{1}{2} (1 - \text{sign}(\lambda)) \\
t^* & \leftarrow [\lambda \theta^T x + \mu] \\
\end{align*} \]

The roles of the client and the server are interchanged, compared to Fig. 4: so \( [\cdot] \) and \( \{\cdot\}_s \) are interchanged and so are \( \delta_C \) and \( \delta_S; s = 1 - 2\delta_C \).

In Step 7, we abuse the \( \hat{y} \) notation to mean either the input to the next layer or the final output.

---

(a) Core version.

---

(b) Heuristic version.

Fig. 8: Privacy-preserving sign evaluation with inputs and outputs encrypted under the client’s public key. This serves as a building block for the evaluation over encrypted data of the sign activation function in a neural network and shows the computations and message exchanges for one unit in one hidden layer.
The main homomorphism characteristics of this scheme are summarised as follows:

\[
\begin{align*}
\|m_1 + m_2\| &= \|m_1\| \oplus \|m_2\| = \|m_1\| \cdot \|m_2\| \mod N^2; \\
\|m_1 - m_2\| &= \|m_1\| \oplus \|m_2\| = \|m_1\| / \|m_2\| \mod N^2; \\
\|a \cdot m\| &= a \odot \|m\| = \|m\|^a \mod N^2.
\end{align*}
\]

Remark 4. It is interesting to note that the new protocols readily extend to any piece-wise linear function, such as the clip function \(\text{clip}(t) = \max(0, \min(1, \frac{t + 1}{2}))\) (a.k.a. hard-sigmoid function). Indeed, as shown in [5], any piece-wise linear function \(\mathbb{R} \to \mathbb{R}\) with \(p\) pieces can be represented as a sum of \(p\) ReLU functions.
Fig. 9: Privacy-preserving ReLU evaluation with inputs and outputs encrypted under the client’s public key.
5.2 Graphs

We implemented the protocols presented in the previous sections using the Python (version 3.7.4) programming language and the GNU multiprecision arithmetic library (GMP version 6.1.2) on a 64-bit machine equipped with an Intel i7-4770 processor running at 3.4GHz. The GMP library is essentially used for generating the prime numbers required for the keys and for performing modular exponentiation of large integers. We used a bit precision of $P = 53$ (see Section 2.2), which corresponds to the number of significant bits for typical IEEE-754 floating point numbers supported by Python.

We tested the protocols using randomly generated models and also models based on the Enron-spam data set [24], a standardized audiology data set [28], a credit approval data set [1], a dataset of human activity recognition using smartphones [4], and the breast cancer database from University of Wisconsin Hospitals, Madison [31]. Performance measurements for various key sizes are presented in Fig. 10, Fig. 11, Fig. 12, Fig. 13, and Fig. 14. Computing times are average over 100 iterations of each protocol on each model. The computing time depends mostly on modular exponentiation of large integers and is linear in the size of the model.

We selected the different key sizes to adequate protection until years from 2020 to 2050 using Lenstra’s method [22]. Those key sizes correspond to a security parameter $\kappa$ between 82 and 102 which means that we compare between 193 and 221 bits (depending on the number of features) when using the DGK+ protocol.

5.3 Estimation of Message Sizes

The size of exchanged messages highly depends on the implementation and the encoding used. We chose to give a theoretical estimate of the size of messages exchanged during the protocols.

In order to give the reader a concrete idea of size the of the messages we provide numerical estimates. For those, we imposed a strong encryption for Paillier’s algorithm and choose $\ell_M = \log_2(M) = 2048$ bits, corresponding security parameter $\kappa = 95$ (see [22]). With Paillier’s scheme the size of ciphertext is $2\ell_M$ bits. We selected a model with $d = 30$ features. To get a bit-size estimate $\ell$ of the upperbound on inner products, we assumed that model weights and input data are normalised so that $|x_i| \leq 1$ and $|\theta| \leq 1$ when considering their real value or equivalently $|x_i| \leq 2^P$ and $|\theta| \leq 2^P$ when considering their integer representation (see Section 2.2). Hence $B = (d+1)2^P$ and $\ell = 2P + \lceil \log_2(d+1) \rceil = 111$. In the case of feed forward neural networks, we chose $L = 3$ and $d_l = d = 30$ ($0 \leq l \leq L$).

Message sizes and their numerical estimates are summarised in Table 1.

6 Conclusion

In this work, we presented several protocols for privacy-preserving regression and classification. Those protocols only require additively homomorphic encryption and limit interactions to a mere request and response. They are secure against semi-honest adversaries. They can be used as-is in generalised linear models (including logistic regression and SVM classification) or applied to other machine-learning algorithms. As an illustration, we showed how they nicely adapt to binarised neural networks or to feed-forward neural networks with the ReLU activation function.
